Counterintuitive Pulmonary Nodules in Rheumatoid Arthritis

**Nódulos pulmonares contraintuitivos en artritis reumatoide**

*To the Editor,*

Rheumatoid arthritis (RA) is a significant cause of morbidity and mortality in developed countries, with a prevalence of 0.5%–1% and an incidence of 5–50 per 100,000. Nodulosis is the most common extra-articular manifestation and occurs in 25% of RA patients.1,2 Pulmonary manifestations are broad and include necrobiotic nodules, infections, drug induced lung injury, obliterative bronchiolitis, interstitial lung disease, bronchiectasis, and malignancy. Tumor necrosis factor (TNF) is an overexpressed proinflammatory cytokine in RA patients, and the American College of Rheumatology has formal recommendations on the use of anti-TNF biologic agents in RA patients with poor prognostic factors. We report a case of a 50-year-old female developing multifocal nodular consolidations, with and without cavitation (Fig. 1A and C), one month after initiation of etanercept. Immunosuppressive drugs were suspended and a bronchoalveolar lavage of the left upper lobe and lingula were negative for an infectious etiology. Devoid of a confirmed infection, her RA medications were restarted, except for etanercept. Serial CT imaging demonstrated interval regression of the nodules. Radiographic changes were seen at the two-month follow up CT, and have remained unchanged at nine months (Fig. 1B and D).

Etanercept-associated nodular disease case reports have varied from new pulmonary nodules with histopathology typical of pulmonary RA nodules, histopathology consistent with sarcoidosis, and histopathology of lymphohistiocytic infiltrates not typical of either.3,4 Treatments for etanercept-associated PN have varied, but typically involve corticosteroids and drug withdrawal. There have also been two case reports highlighting the evolution of the nodules with continued etanercept therapy, illustrating the regression of nodules as well as stability of nodules without progression despite continued etanercept therapy.5

This case exemplifies that a recombinant human TNF receptor fusion protein may contribute to the counterintuitive formation of granulomatous disease and pulmonary nodules. Many mechanisms have been proposed, but the exact mechanism leading to pulmonary nodules is not currently known. It has been proposed that the increased size or formation of pulmonary nodules may be related to the increased size of necrotic centers, a result of the reduction of soluble TNF leading to an exaggerated or altered effect on other inflammatory pathways, or even directly related to the RA progression and not directly related to the therapeutic agent.1,4

In conclusion, we appreciate that PN is not uncommon in RA patients, but recommend that etanercept-related PN be considered as part of the differential diagnosis. Bronchoalveolar lavage should remain integral to the evaluation, but if unrevealing it would be reasonable to withhold etanercept followed by repeat imaging in 6–8 weeks. If the nodules are stable or regress, than serial imaging would be a reasonable approach. Progressive disease should be further investigated. Consideration of etanercept as the etiology of new pulmonary nodules may decrease morbidity associated with unnecessary invasive diagnostic procedures associated with nodule work up.

Fiberoptic Bronchoscopy Findings in Children With Stridor in a Tertiary Hospital5

Hallazgos fibrobroncoscópicos en pacientes estudiados por estridor en un hospital de tercer nivel

To the Editor,

Stridor is a musical sound generated by the rapid, turbulent passage of air through a narrowed section of the airways.1–3 Patients with stridor should be evaluated with a complete clinical history and physical examination.2 The characteristics of stridor indicate the level of the lesion.1,2 When it occurs on inspiration, the lesion is generally supraglottic, when it is inspiratory, it is located in the intrathoracic airway,1,2 and when stridor is biphasic, the stenosis is located in the trachea.2

We performed a descriptive study of children with stridor undergoing fiberoptic bronchoscopy (FB) from January 2009 to December 2013, analyzing sex, age, underlying disease, symptoms, type of stridor, fiberoptic bronchoscopy findings, treatments and FB yield. We used an Olympus® fiberoptic bronchoscopy (2.8, 3.6 and 4.8 mm).

We performed 593 FBs, 138 (23%) for stridor; 63% in infants younger than 1 year, 14% in children between 1 and 2 years, 17% between 3 and 7 years and 6% in patients older than 8 years; 58% were male. The most predominant form of stridor was inspiratory (78%). Diagnostic yield was 95%, i.e., 130 patients obtained diagnostic or therapeutic benefit, while 18 of those patients required a repeat FB (12%). Most (81%) had underlying disease (Table 1). Fiberoptic bronchoscopy findings are summarized in Table 1. In 91% of cases we took a “wait and see” approach; 12 patients (9%) needed surgical treatment (6 required tracheoplasty, 2 aortopexy, 2 tracheostomy, 1 uvulotomy, and 1 laser ablation) and 2 patients with subglottic hemangioma received propanolol, with good response. A total of 8% of the patients had mild, self-limiting desaturations.

Stridor is a symptom which requires an etiological diagnosis1–3 based on clinical history, physical examination, and direct evaluation of the airway1 with fiberoptic bronchoscopy.1–4 This is generally performed under spontaneous breathing, allowing an anatomical and functional examination of the airways.2,3 Respiratory pediatricians, ENT specialists, pediatric surgeons and/or anesthetists must work closely together to maximize the benefit of this procedure and ensure it is correctly performed. In our hospital, FB is performed in collaboration with anesthetists, who generally apply sevoflurane. In our opinion, the airway must be examined in its entirety.

Like other authors, our case series showed that laryngomalacia was the most common finding in infants with inspiratory stridor,1–3 and this condition generally resolved with a “wait and see” approach, since laryngomalacia is a result of immature laryngeal structures.2,3 The second most common disorder encountered was subglottic stenosis (15%). This percentage was high, but in our opinion there was some element of bias, as our hospital is the respiratory referral center for the south of Spain. Stridor can be caused by congenital or acquired diseases.2 The most common type is biphasic stridor associated with varying degrees of clinical airway obstruction.2 In our group of patients, all, except 1, developed symptoms after intubation. Subglottic stenoses with Cotton grades III and IV are treated by surgery, as was the case in 9% of our patients. The most common technique used was tracheoplasty with rib cartilage graft (5%).

In our opinion, FB is the technique of choice in the diagnosis of airway disorders,2,5 as it is safer and less aggressive than rigid bronchoscopy. We recommend that FB be performed in any child who presents with stridor, since this symptom is generally an indication of a banal disorder, but it can mask a life-threatening disease.1,3,5
