Endobronchial Actinomycosis Associated With an Inorganic Foreign Body

We report the case of a 79-year-old man with a history of laryngeal cancer who underwent total laryngectomy in 2010 with tracheotomy and subsequent placement of a voice prosthesis in 2012. He attended the emergency room for chest pain and dyspnea. CT-angiogram of the chest revealed incomplete obliteration of the left principal bronchus (LPB), and an image of a metallic foreign body in the interior of the airway was identified, along with distal alveolar infiltrate in the left lung base (Fig. 1).

Fiberoptic bronchoscopy showed a foreign body (voice prosthesis) occupying the LPB surrounded by a significant granulomatous reaction, which could be extracted with biopsy forceps (Fig. 1).

Histopathological examination of the bronchial biopsy revealed a nonspecific inflammatory process with presence of foreign material and abundant colonies of actinomyces.

Endobronchial actinomycosis is very rare and has occasionally been described in association with the aspiration of a foreign body. In our case, the foreign body was inorganic — only 3 cases of this association have been reported in the literature. The patient reported that he had aspirated the voice prosthesis over 24 months previously, without symptoms. The patient did not require antibiotic treatment after the foreign body had been completely extracted by bronchoscopy.
